Special Paper – Large Meteorite Impacts
submitted: 25 November 2003

ABSTRACT

We have done lithophile- and siderophile-element analyses of target rocks, and ballistically dispersed impact-melt particles and metallic spherules from Meteor Crater, AZ. The upper Moenkopi Formation has a unique lithophile-element signature that confirms it as a major component of the impact-melt particles. The Kaibab Formation is very heterogeneous, containing dolomite-rich and quartz-rich layers. The lithophile-element compositions of the impact-melt particles can be entirely explained as mixtures of Moenkopi and Kaibab depleted in CO₂. The Toroweap and Coconino Formations are not required components, but small contributions from them are not excluded. We conclude the impact-melt particles were formed in the upper portion of the section, above the sandstone units.

The impact-melt particles on average contain about 14% Canyon Diablo meteorite material. Most siderophile-element ratios of the impact-melt particles are unchanged from those of the projectile. Many samples are depleted in Au, with the most extreme depletions found in impact-melt particles with the highest Kaibab component. Because Kaibab rocks are higher in Br than other target rocks, we suggest loss of volatile Au halides may have caused the fractionation.

Ballistically dispersed metallic spherules are enriched in Co, Ni, Ir and Au compared to Canyon Diablo metal. Element/Ni ratios deviate slightly from Canyon Diablo ratios, and are inversely correlated with oxidizability. We attribute this to partial oxidation of molten metal spherules during flight. Spherule compositions suggest slight selective melting of graphite-troilite-schreibersite inclusions of the projectile consistent with enhanced shock melting of these lower density inclusions.

“Special features, such as the presence of layering or volatiles in the target are not shown here. The effects of such circumstances are largely unknown at present.”

Impact Cratering. A Geologic Process, p. 48

INTRODUCTION

In support of the push to put a man on the moon in the 1960s, planetary sciences underwent a period of vigorous growth. One result of this was the recognition that impact processes play an important role in modification of the surfaces of planetary bodies. All solid surfaces in the solar system are scarred by impacts, from Mercury, to the moons of Neptune. In addition, impact melts, melt breccias, regolith breccias and shock-damaged rocks are common among the returned lunar samples and almost all meteorite types.

The study of impact processes has generally progressed along a five pronged front: (i) field and petrologic study of terrestrial impact craters and their products, (ii) laboratory-scale impact experiments, (iii) large-scale explosion experiments, (iv) theoretical modeling of the impact process, and (v) astronomical and spacecraft study of craters on planets, moons and asteroids (see Melosh, 1989). Geochemical studies generally have contributed to the identification of a meteoritic signature in impact melts (e.g., King et al., 2002), attempted to identify the type of impactor (Morgan et al., 1975; Palme et al., 1978), or established the process of mixing of target rocks to form unusual impact-melt rocks (e.g., Dence, 1971; Grieve, 1982; Simonds et al., 1978). Chemical studies aimed at a more detailed understanding of the cratering process have been limited for several reasons. Older structures have been eroded and/or buried, making detailed reconstruction of the pre-impact chemical stratigraphy difficult. Impact-melt sheets in larger structures may have suffered hydrothermal alteration (see Hagerty and Newsom, 2003), which may have altered the composition of the melt sheet. Finally, older and larger

structures generally do not have preserved meteoritic material available for study (Grieve, 1991), so the type of impactor cannot be confidently identified. As a consequence, the depth of the melt zone is poorly defined, and there are substantial uncertainties regarding the degree of fractionation of impactor and target rocks during melting.

Recently, studies have been done on a few younger, smaller impact craters for which projectile material is also available. Attrep et al. (1991) presented the results of the geochemical study of a limited number of samples from Henbury and Wolfe Creek Craters. These authors showed that siderophile-element ratios in “impactites” are fractionated relative to those of the preserved projectile material. We did an extensive study of samples from Wabar Crater that confirmed that siderophile-element fractionations occurred during formation of impact-glass particles (Mittlefehldt et al., 1992). We further suggested that because lithophile elements were not fractionated in the glasses, fractionation of the siderophile elements must have occurred before mixing of the projectile and target materials. We also inferred that projectile material was preferentially mixed with the upper stratigraphic horizons of the target.

We have continued our study of natural impacts through field, petrologic and geochemical study of Meteor Crater, Arizona, the largest crater with associated preserved projectile material (Grieve, 1991). Meteor Crater is almost an ideal candidate for such study as the stratigraphy is variegated, allowing a more detailed look at the projectile-target interaction; it is young and fresh; abundant impact-melt material already resides in collections and is easily obtained for study; and remnants of the projectile have been well characterized. We have pursued a number of studies in our effort to understand the impact process at Meteor Crater. The results of our detailed study of the mineralogy and major-element chemistry of the target rocks and the petrology of the impact glasses have been reported (Hörz et al., 2002; See et al., 2002).

Here we present our completed study of lithophile and siderophile elements for target rocks, impact-melt particles, and metallic spherules.

GEOLOGIC SETTING AND BACKGROUND

Pre-impact target

Meteor Crater is one of the best-studied terrestrial impact structures, and the detailed pre-impact stratigraphy and structure are well known. The synopsis given here is taken from Roddy (1978), Roddy et al. (1975) and Shoemaker (1963; 1987). See et al. (2002) presented details of the major-element chemistry and mineralogy of a stratigraphic sequence systematically collected from the crater walls. These references should be consulted for detailed discussion of the target rocks.

Meteor Crater was formed in a generally flat-lying sequence of Mesozoic and Paleozoic sediments. The uppermost unit, the Triassic Moenkopi Formation, consists of calcareous sandstone and siltstone. This unit is patchy and varies considerably in thickness from about 1 to 24 m near the crater, but is estimated to have averaged ~8.5 m in thickness in the area destroyed by the impact (see Roddy, 1978). In the crater walls, the Moenkopi systematically varies from more carbonate-rich at the top to more quartz-rich at the bottom (See et al., 2002). Below the Moenkopi is the Permian section starting with the Kaibab Formation, an approximately 80 m thick carbonate sequence consisting largely of sandy dolomite, but including some sandstone. The composition of this unit is highly variable reflecting wide ranges in quartz and dolomite content; calcite is a minor component. The upper half of the unit is richer in carbonate than is the lower half (See et al., 2002). Below the Kaibab is the thin, ~1.5 m thick Toroweap

Formation consisting dominantly of dolomitic sandstone. The bottom of the crater is in the ~220 m thick Coconino Formation which is composed of very pure sandstone with SiO₂ contents >95 wt%. Below the Coconino is the Permian Supai Formation of sandstone and siltstone. The Supai is believed to be brecciated, but there is no evidence that the transient crater excavated it.

Canyon Diablo iron meteorite

Meteor Crater was formed by the impact of the Canyon Diablo IAB iron meteorite, which is estimated to have been ~33 m in diameter for an assumed impact velocity of 15 km/sec (Roddy, 1978). The IAB group is one of the non-magmatic iron meteorite groups, so-called because their chemical characteristics are not those of metal formed by fractional crystallization of a metallic core (Scott and Wasson, 1975). The IAB irons, especially Canyon Diablo, have been extensively studied. Wasson and Ouyang (1990) have done a detailed compositional study of Canyon Diablo, while Choi et al. (1995) have presented a thorough study of the composition of the metal phase of most IAB irons. Choi et al. (1995) present an average composition of Canyon Diablo based on 64 analyses, which we use here in discussions of our siderophile-element data for impact-melt particles and metallic spherules. The composition of the Canyon Diablo iron, with 70 mg/g Ni, is typical of that of the majority of IAB irons.

Buchwald (1975) gave a detailed description of the petrology of Canyon Diablo and most other IAB irons. It is a coarse octahedrite containing about 8.5% by volume of troilite-graphite inclusions. These inclusions have varying ratios of troilite to graphite, and include a suite of minor phases. They are typically surrounded by schreibersite and cohenite (Benedix et al., 2000; Buchwald, 1975). Buchwald (1975) estimates that on average, the inclusions have roughly equal amounts of troilite and graphite by volume. Silicate inclusions are present in many members of

the IAB group (e.g., Benedix et al., 2000; Mittlefehldt et al., 1998). Although not commonly seen in Canyon Diablo specimens, Buchwald (1975) reports that silicates are present in some troilite-graphite nodules. The silicates in IAB irons are mostly chondritic in composition, although other types also occur (Benedix et al., 2000; Bunch et al., 1970).

Meteor Crater and impact products

Meteor Crater is a classic bowl-shaped impact crater approximately 1 km in diameter, although structural controls in the rocks in the target area give it a squarish shape in map view (Roddy, 1978). The crater was formed approximately 50 Ka ago (Nishiizumi et al., 1991; Phillips et al., 1991). Shocked and frothy Coconino sandstone occurs in the crater floor below a layer of alluvium, but no continuous impact-melt sheet is present (Roddy et al., 1975). Shocked and brecciated target rock occurs on the crater floor, in the walls and in the overturned flap (Roddy et al., 1975). Impact melt composed of mixtures of target rock and projectile are confined to particles up to a few cm in size ballistically dispersed over the plains surrounding the crater (Nininger, 1956). Metallic spherules a few mm in diameter are also found on the surrounding plains (Nininger, 1956). These are melt-droplets of the Canyon Diablo iron and are not mixed with target rock (Blau et al., 1973). Finally, some samples of Canyon Diablo show petrographic evidence for shock deformation superimposed on the normal structure of the iron. These are solid fragments of the impactor spalled from the backside of the projectile as the shock wave reflected off the free surface (Buchwald, 1975).

SAMPLES AND ANALYTICAL METHODS

Samples

We have analyzed three types of materials for this study: (i) representative samples of the target rock, mostly from within the crater or the overturned flap, (ii) ballistically dispersed impact-melt particles, and (iii) metallic spherules. A few of the target-rock samples analyzed during the initial stages of this study were collected solely as representative hand samples of the Kaibab and Coconino Formations, and are from undocumented locations. A second set of documented samples from within and around the crater was collected specifically to obtain a representative suite of the lithologic diversity within the crater. Brief descriptions of these samples are given in Appendix 1. A third set of samples was collected specifically to obtain a measured stratigraphic sequence from within the crater for geochemical and mineralogical characterization. The samples, major-element analyses by x-ray fluorescence (XRF), and mineralogy determined by x-ray diffraction (XRD) of these are given in See et al. (2002). The impact-melt particle and metallic spherule samples were obtained from the collection of the Center for Meteorite Studies, Arizona State University. H.H. Ninninger collected these samples from the plains surrounding the crater, but their precise collection locations are not known. The impact-melt particles were selected by one of us (FH) to represent the range of materials in the collection. Brief macroscopic descriptions of these are given in Appendix 2. The petrology of the impact-melt particles has been discussed in detail in Hörz et al. (2002).

Analytical methods

The target-rock and impact-melt particle samples were analyzed by instrumental neutron activation analysis (INAA) at Johnson Space Center (JSC) in a series of irradiations. Some of the target rocks, those labeled Ma, Ka, Ta, Ca, etc., are splits of the pooled “subsection” samples of See et al. (2002). For the other target rocks, several grams of each sample were ground and

homogenized, and splits taken for analysis. Some of the impact-melt particles contained variable amounts of adhering alteration material, or fine-grained alluvial or soil particles. These contaminants were removed by scraping with a dental pick and ultrasonication in distilled water. The impact-melt particles were then coarsely crushed and the cleanest impact-melt material was handpicked from among the larger fragments. Many of the impact-melt particles are finely vesicular, and alteration material was found even in interior vesicles. It proved impossible to eliminate all of the alteration material. The occurrence of alteration material even in tiny interior vesicles indicates that it likely formed from elements leached out of the glass. Samples of alteration material from three impact-melt particles were analyzed in order to evaluate the potential effects of this material on analyses. For the larger impact-melt particles, clean material was crushed and homogenized and splits taken for INAA. For the smaller particles, the entire clean sample was used for INAA.

The samples, standards and international standard rocks used as controls were sealed in ultra-pure silica glass tubes, and irradiated at the University of Missouri Research Reactor Facility. The samples were counted three or four times at differing times after irradiation to obtain data for nuclides of differing half-lives. Irradiation times, neutron fluxes and counting schedules were slightly different for the different irradiations depending on the nature of the total sample package. Data reduction was done using standard JSC procedures (Mittlefehldt and Lindstrom, 1991, 1993). The impact-melt particles and some target rocks have high Mg contents and low Na contents. A correction to the data was applied to account for Na produced by (n,p) reactions on Mg. The ultra-pure silica contains a tiny amount of La that can significantly affect the data for very small or La-poor samples. A blank correction was made as needed.

The metallic spherules were analyzed by INAA at UCLA in the mid 1970s. The samples consisted of metal cores with oxide coatings. Following Kelly et al. (1974), the samples were abraded in a mixer-mill with a sandpaper lining until the oxide coatings appeared to have been removed. The spherule samples, six samples of the North Chile hexahedrite (IIA iron) Tocopilla serving as standards, and the IVA iron meteorite Rembang serving as a control, were irradiated at the Ames Laboratory Research Reactor at a flux of $2 \times 10^{13} \text{ n cm}^{-2} \text{ sec}^{-1}$ for 10 hours, and counted several times to obtain data for elements of differing half-lives. Subsequently, four of the samples were reirradiated at the UCLA reactor for radiochemical determination of Ga and Ge following the procedures of Wasson and Kimberlin (1967).

Splits of the larger impact-melt particles were fused to glass on a Mo metal strip in an Ar atmosphere following the procedure of Brown (1977) and major elements were determined by electron microprobe analysis (EMPA). This procedure was designed for use with basaltic compositions, and the unusual compositions of the impact-melt particles caused two problems. First, the impact-melt particles are not in internal equilibrium, especially with respect to oxidation state – they contain Fe^{3+} , Fe^{2+} and Fe^0 (see Hörz et al., 2002). Because of this, Mo from the strip was oxidized and dissolved in the glass at up to a few wt% in the most extreme cases. Some of the Fe remained in the metallic state, and thus, was not part of the homogeneous glass. For this reason, there is poor agreement between FeO determined by INAA and EMPA. However, the major-element data are used to determine which of the target rocks contributed to the impact-melt particles. The target rocks are generally poor in FeO, and most of the Fe in the impact-melt particles is derived from the impactor (See et al., 2002; this study). To first order, FeO can be ignored in evaluating target-rock contributions to the impact-melt particles. The

glass beads were analyzed with the JSC SX100 electron microprobe using a 15kV potential, 15 nA sample current, and the electron beam rastered over a 10x10 μm area.

See et al. (2002) presented major-element analyses by XRF of many of the target rocks studied here. Additional target-rock samples plus a composite of 15 impact-melt particles were analyzed as part of this study. The analytical methods follow standard procedures used at Franklin and Marshall College, described in detail by Boyd and Mertzman (1987). An exception to these procedures is that the samples were first ground and homogenized in an agate mortar and pestle at JSC, and splits sent to Franklin and Marshall College for analysis. Final grinding and sieving were done at Franklin and Marshall. Major-element contents were determined by XRF analysis, with all Fe determined as Fe_2O_3 . The ferrous iron content was determined by titration, and loss on ignition was determined by heating an aliquot at 950°C for one hour.

RESULTS

The results of our analyses are presented in Tables 1-5. Table 1 presents the major-element analyses of the target rocks plus the composite impact-melt particle (H11). The XRF analysis determines major elements on a volatile-free basis, and all Fe as Fe_2O_3 . In Table 1 the data have been recast to a volatile-bearing basis, and with Fe split between FeO and Fe_2O_3 as determined by titration. The low sum for the analysis of the composite impact-melt particle is an artifact of the recalculation. It has a high total Fe content, with much of it ferrous – the XRF sum was 99.31. The INAA data on target rocks, including those studied by See et al. (2002) are given in Table 2. Our INAA data on impact-melt particles are given in Table 3, and major-element analyses of select impact-melt particles determined by EMPA on fused beads are presented in Table 4. These latter analyses are normalized to sum 100%. As mentioned, the

analyses included variable amounts of MoO₂ (<0.01 to 4.56 wt%) derived from the strip heater, and the Fe in the glass likely is a mixture of FeO and Fe₂O₃. These analyses are primarily used to evaluate which of the target rocks dominate in the impact-melts, and devolatilized, Fe-free (projectile-free) compositions are needed for this evaluation. Table 5 contains our INAA data on the metallic spherules. We have also done INAA on a few miscellaneous samples from the impact-melt particle suite – a lithic clast, samples of secondary alteration products and an oxide bead. These data are given in Appendix 3 for completeness.

DISCUSSION

There are several problems associated with comparing geochemical data on the target rocks with those on impact-melt particles. The high-temperature formation of the impact-melt particles caused devolatilization of carbonates and hydrous phases of the target components, and mixing of projectile material into the impact-melts diluted the target components. Because of this, when comparing the compositions of target rocks and impact-melt particles, we use normalized compositions. The impact-melt particle compositions are normalized to Fe-Ni-Co-free basis. The volatile content of these particles is not known, but they should be nearly volatile-free. We arbitrarily use the LOI determination on the composite of 15 impact-melt particles (H11, Table 1) to correct for volatile content. The target-rock compositions are normalized to a volatile-free basis using the LOI determinations, and to an iron-free basis to make them more directly comparable to the impact-melt particles. These corrected impact-melt and target-rock compositions are referred to as “adjusted” compositions.

The data on impact-melt particles given here are not directly comparable to the impact-melt glass compositions reported by Hörz et al. (2002). The latter are for EMPA of glasses,

while the data presented here are for bulk particles, including glass, quenched mineral phases, undigested clasts and remnant metal and sulfide beads.

Geochemical stratigraphy of Meteor Crater

Previously, we established that the upper portion of the target stratigraphy shows substantial major-element compositional heterogeneity (Hörz et al., 2002; See et al., 2002). The Moenkopi Formation shows a general decrease in CaO and LOI, and an increase in SiO₂ from top to bottom, indicating increasing quartz sand and decreasing calcite with depth. The Kaibab exhibits substantial fluctuation in SiO₂ and MgO+CaO throughout the section reflecting variations in quartz sand and dolomite. On a finer scale, we found that the quartz content of the Kaibab varies from almost 100% to ~15% within the section (Hörz et al., 2002; See et al., 2002). These variations are non-systematic – the Kaibab sample with the lowest quartz content is from immediately above a sample with one of the highest (see Hörz et al., 2002, Fig. 15, samples K106.2 and K104.7). The Toroweap and Coconino are distinguishable from other target rocks only by their high SiO₂ contents.

Variations in adjusted major-element content of the target rocks with depth in the crater are shown in Fig. 1. The Moenkopi is distinct in having much higher Ti and Al contents than all other units, while the Kaibab is distinct in having a much higher Mg content, and generally lower but variable Si content. The non-systematic variation in Si in the Kaibab shows up in the depth profile (Fig. 1). The high Al content of the Moenkopi indicates a higher terrigenous component (e.g., clays) in it than in other units in the section. This is also seen in trace-element contents (Fig. 2). The Moenkopi is rich in Sc, the rare-earth elements and Ta compared to the other units. The two lowest samples from the Moenkopi also are rich in Hf, but the upper portion has Hf

contents like those of the Kaibab. The Kaibab is distinct in showing a general increase in U content with depth, and the lower portion of the section has the highest U content in the depth profile (Fig. 2).

The Toroweap and Coconino are lower in all major and trace elements measured when adjusted to a volatile- and iron-free basis, excluding Si (Figs. 1, 2). Hence, these units would only act as diluents in lithophile-element mixing relations should they be a component of the impact-melt particles.

Lithophile elements and target rock mixing

Kargel et al. (1996) suggested that impact-melt particles from Meteor Crater are composed of mixtures of projectile and rock from the Kaibab Formation, with no clear signature for either Moenkopi or Coconino rocks in the mix. Our preliminary synopsis of the compositions of target rocks and impact-melt particles led us to suggest that the Moenkopi and Kaibab strata are the primary terrestrial components in the impact-melt particles (Mittlefehldt et al., 2000). This was supported by our modeling of the major-element compositions of glasses contained in the impact-melt particles. We identified three distinct melt compositional types and concluded that different mixtures of Moenkopi and Kaibab components could explain the glass compositions, with Moenkopi composing as much as half of the target component in some glasses (Hörz et al., 2002). While we could not exclude Coconino as a minor component of some glasses, the data do not require it. We suggested that the melt zone was a relatively small fraction of the transient crater volume, and that melting occurred at depths of <30 m for many, and possibly all, of the glasses (Hörz et al., 2002).

Mixing relations for major elements between target rocks and bulk impact-melt particles are shown in Fig. 3. All impact-melt particles in the three binary systems shown – Mg-Al, Ca-Al and Ti-Si – fall within a field defined by Moenkopi and Kaibab samples. No impact-melt particles have excesses in Si or deficits in the other elements that would require addition of Toroweap/Coconino into the mix. However, the scatter in the data would *permit* a small Toroweap/Coconino component. In the Mg-Al plot, we show an expansion of the central portion of the impact-melt field demonstrating that the data range could obscure at most about a 10% contribution by Coconino to the impact-melts. Because there are no distinguishing elements in the Coconino or Toroweap, they are difficult to fingerprint in the impact melts.

Lithophile-trace-element contents of impact-melt particles and target rocks are in accord with the inference made from major-element contents. In Ca-Sc and Ca-Ta plots, the impact-melt particles plot between the fields occupied by Kaibab and Moenkopi rocks, and away from the trace-element-poor Toroweap and Coconino (Fig. 4). The Toroweap and Coconino rocks have the lowest lithophile-trace-element contents (Table 2, Fig. 2), and the lithophile-trace elements are generally correlated in the target rocks. Because of this, on diagrams such as Ta vs. Sc (Fig. 4), Toroweap and Coconino rocks could be interpreted as one end member of a mixing trend. However, their stratigraphic location argues against this. The Ta-Sc plot clearly shows that the topmost unit, the Moenkopi, is a significant component of the impact-melts, and that all of them lie between the fields for Moenkopi and Kaibab rocks. Because the Kaibab is a thick unit between the Moenkopi and Toroweap/Coconino, it is more plausible that the Kaibab is the most significant trace-element-poor component in the impact-melts.

The lithophile-element contents of some impact-melt particles are outside the ranges for Moenkopi and Kaibab rocks. For example, the adjusted La content of a few are higher than

observed in our suite of Moenkopi rocks, while the U and K contents of many are lower than those of the Kaibab or Moenkopi rocks (Fig. 5). The high La contents determined for a few impact-melt particles relative to Moenkopi rocks likely indicates that our sampling of this formation at ~2.5 meter scale was inadequate to define the effective compositional heterogeneity of the formation.

The low K and U contents for many of the impact-melt particles suggest possible element fractionation during or after their formation. Potassium and the other alkali elements potentially could have been partially volatilized during the high temperature phase. Uranium is normally considered a refractory element, but some U halides are quite volatile (Lide, 2001). The Kaibab formation typically contains 1-2 $\mu\text{g/g}$ Br (Table 2) and likely much higher contents of Cl (seawater Cl/Br ~290). Hence, formation and loss of species such as UCl_4 (boiling point 1064°K , Lide, 2001) may have occurred. Alternatively, the low K and U contents might indicate loss during low-temperature alteration of glasses in the particles. We documented late oxidation of Fe in glasses (Hörz et al., 2002), and vesicles in the interiors of some impact-melt particles contain secondary phases indicating leaching from the particles. Uranium is subject to oxidation and mobilization during alteration, and alkali elements are typically easily mobilized during alteration. Regardless, the K and U contents of the impact-melt particles do not indicate that Toroweap or Coconino are significant components. Those impact-melt particles with the lowest K and U contents, like those of Toroweap and Coconino rocks, nevertheless contain high Ca contents demonstrating a large Kaibab component.

Based on the major-element compositions of glasses in impact-melt particles, we concluded that mixing rocks from the upper 30 m of the target formed some of them (Hörz et al., 2002). We have not attempted to do formal mixing calculations based on the major- and trace-

element data for bulk impact-melt particles presented here, but our earlier conclusion is compatible with them. We also concluded that while the higher SiO₂ contents of some of the glasses *may* indicate a small component of Coconino is present, this was not *required* by the data. As shown in Fig. 3, the major-element contents of the impact-melt particles would allow for as much as ~10% Coconino. However, because all major- and trace-element data (excluding potentially mobile elements such as K and U) for the impact-melt particles lie between the fields for Moenkopi and Kaibab, we believe it to be more plausible that only these two rock units were mixed in the melt zone to form the particles, and thus the melt zone extends no deeper than the base of the Kaibab, ~85 m at most.

Siderophile elements and projectile-target mixing

The impact-melt particles contain a substantial projectile component. The siderophile-element contents normalized to the mean Canyon Diablo metal composition (Choi et al., 1995) show that Co, Ni and Ir contents reach 22-27% of that of the projectile (Fig. 6). However, because CO₂ was volatilized from the carbonate-rich target rocks, the actual maximum projectile component mixed with the bulk target is less. There is a fairly good correlation between target-rock CaO+MgO and LOI (See et al., 2002), and we have used this to estimate the mass of target rock lost during impact melting for those particles for which we have major-element data (Table 4, plus H11, Table 1). For these we estimate that between 7-15% of the mass was lost, and that the maximum projectile component based on Co, Ni and Ir was thus between 20-22%. Using an average mass correction of 11%, we find that the impact-melt particles contain, on average, 14% projectile component. This is higher than we found for ballistically dispersed impact-melt particles from Wabar Crater (Fig. 6). There we found average projectile components of ~7% and

~9% for large and small glass beads, with a maximum of ~17% for one small bead (Mittlefehldt et al., 1992).

There are very few other craters where both impact melts and impactor are preserved, and very few analyses of impact melts have been done. Attrep et al. (1991) found projectile components of ~4% and ~10% (based on Co and Ni) for two impact melts from Wolfe Creek Crater (Fig. 6), and <1% for three impact melts from Henbury Crater. The types of impact melts analyzed from these two craters were not specified. The very low projectile component in the Henbury Crater samples most likely indicates that they represent massive-melt objects. We previously showed that large melt specimens (>100 g) from Wabar contain a much smaller projectile component than do ballistically dispersed, mm-sized melt beads (Mittlefehldt et al., 1992). The Henbury samples will not be discussed further.

The Meteor Crater impact-melt particles have relatively unfractionated Co/Ni and Ir/Ni ratios over the range of projectile contents, but Au is strongly fractionated as exemplified by Au/Ir ratios (Fig. 6). The Au fractionation is independent of the amount of projectile component in the particles. Samples with projectile-normalized Au/Ni ratios as low as 0.03 have normalized Co contents ~20% that of the Canyon Diablo iron, and two samples with normalized Au/Ni of 0.82 and 0.90 have normalized Co contents of 7% and 10% that of the projectile (Fig. 7). This shows that the Au fractionation is independent of the target-projectile mixing process, i.e., fractional condensation from a vapor cloud or selective vaporization from the impact melts of siderophile elements is not the cause (see Kelly et al., 1974 and Gibbons et al., 1976 for discussions of proposed fractionation processes). This is also suggested by hydrocode simulations of the Meteor Crater impact that show that for plausible impact velocities, projectile vaporization is unimportant (Schnabel et al., 1999).

Two samples have anomalous siderophile-element characteristics. Particle M20 has high Co/Ni and Ir/Ni ratios due to depletion in Ni – increasing Ni by a factor of 2.5 brings this sample within the range of other impact-melt particles for Co/Ni and Ir/Ni. Particle M20 contains clear glass and two types of altered glass intimately mixed (Hörz et al., 2002). The clear glass contains ~7% projectile component, and has an Fe/Ni ratio like that of the projectile, while the altered glasses are very iron-rich with Fe/Ni ratios much greater than that of the Canyon Diablo iron (Hörz et al., 2002). The bulk sample studied here is like the clear glass in Fe content, but like the two types of altered glass in Na, K and Ca. Possibly, the anomalous characteristics of M20 may simply reflect heterogeneous distribution of the siderophile elements among different glass types. Particle M12 has a very low Ir/Ni ratio due to an anomalous Ir content. This particle has a Au/Ir ratio like that of the Canyon Diablo iron, but this is anomalous compared to all other impact-melt particles with low Ir and Au contents (Fig. 6). Particle M12 contains only clear glass, with the lowest projectile component among those studied (Hörz et al., 2002). This is also observed in the bulk impact-melt particle, with ~3.5% projectile based on Co and Ni. Note however that the Ir and Au contents are much lower and suggest only ~0.1% impactor (Fig. 6).

The siderophile-element characteristics of the Meteor Crater impact-melt particles show some similarities and some differences with those from Wabar and Wolfe Creek Craters (Fig. 6). Most Wabar samples have Co/Ni ratios significantly elevated above that of the impactor, while only Meteor Crater particle M20 is so endowed. The single Wolfe Creek Crater sample plots close to the impactor line – more data are required to determine whether Co/Ni fractionation occurred at this crater. Most Wabar impact-melt particles have Ir/Ni ratios like that of the impactor. A few have anomalously low Ir/Ni ratios, but none are as anomalous as M12. Both

Wolfe Creek Crater samples show anomalous Ir/Ni ratios, but again, not to the extent of M12. All samples from Wabar Crater and the single sample from Wolfe Creek Crater have Au/Ir ratios less than that of the projectile. Although only three craters have been sampled, and for one only a single sample was analyzed, the data suggest Au fractionation may be a common process occurring during impact melting at terrestrial craters.

Attrep et al. (1991) and we (Mittlefehldt et al., 1992) stated that observed siderophile-element fractionations in terrestrial impact melts indicate that attempts to identify impactor types from analyses of impact melts from the Earth and Moon should be treated cautiously. We still believe this to be true for terrestrial craters. However, the observed fractionations may be uniquely terrestrial, and thus, may not apply to impact melting on the Moon. There is general tendency for those Meteor Crater impact-melt particles with the highest molar $(\text{Ca}+\text{Mg})/\text{Si}$ to have lower normalized Au/Ir ratios (Fig. 8), indicating that those with a higher Kaibab component are more fractionated. Among the target rocks, Kaibab samples have generally higher Br contents (Fig. 8), and Se, a proxy for S, was detected almost exclusively in Kaibab Formation rocks (Table 2). This suggests that the Au fractionation is tied to the volatile content of the target, and that volatile Au complexes may have been formed and lost during impact melting. If true, then siderophile-element fractionation may not occur during impact melting on the Moon.

Unfortunately, the case is not clear-cut. There is substantial scatter in the Meteor Crater data (Fig. 8) that obscures compositional correlations. This may result from the heterogeneous nature of the Kaibab (Figs. 1, 2; Hörz et al., 2002; See et al., 2002), the heterogeneous melting process, or that the trend is not real. Wolfe Creek Crater was formed in Precambrian quartzite, and we have no detailed information on the composition of the target rocks. Wabar Crater was

formed in sandstone and the low Ca contents of Wabar impact glasses and target materials indicate that there was little carbonate in the target (Hörz et al., 1989; Mittlefehldt et al., 1992). We do not have Br or Se data for the Wabar target-rock samples, and thus, cannot compare possible halogen or sulfate contents with Meteor Crater. More data on target rocks and impact-melt particles from additional craters in which the projectile has been preserved are needed to evaluate the cause of Au fractionation observed in impact-melt particles from terrestrial craters.

In our study of Wabar impact-melt particles, we deduced that more projectile material was mixed into melts formed in the upper portions of the melt zone than in the lower portions (Mittlefehldt et al., 1992). The Meteor Crater data give some support to this. The Kaibab rocks have the highest molar $(\text{Ca}+\text{Mg})/\text{Si}$ and $(\text{Ca}+\text{Mg})/\text{Al}$ ratios in the target stratigraphy (Fig. 9). These ratios should then increase in impact-melt particles formed as the melt zone penetrates deeper into the section. Impact-melt particles with $(\text{Ca}+\text{Mg})/\text{Si}$ and $(\text{Ca}+\text{Mg})/\text{Al}$ ratios less than in any of the Kaibab rocks have projectile-normalized Ir contents that are, on average, higher than those with the highest $(\text{Ca}+\text{Mg})/\text{Si}$ and $(\text{Ca}+\text{Mg})/\text{Al}$ ratios (Fig. 9). Remember that the impact-melt particles have had their projectile component enhanced through mass-loss of CO_2 during melt formation, and that samples with higher $(\text{Ca}+\text{Mg})/\text{Si}$ ratios (higher carbonate component) have lost the most mass. Thus, the normalized Ir contents of those samples on the right side of Fig. 9 have been enhanced systematically more by this process than those on the left. The data are broadly consistent with a generally decreasing projectile/target mixing ratio as the projectile penetrates the target. Samples with the highest normalized Ir contents have intermediate $(\text{Ca}+\text{Mg})/\text{Si}$ (~0.5-0.6) and $(\text{Ca}+\text{Mg})/\text{Al}$ (~7-8) ratios (Fig. 9), possibly indicating that the peak projectile/target mixing ratio was reached at some intermediate depth in the melt zone, rather than at the target surface.

Two impact-melt particles, M12 and M20, have lithophile-element contents indicating a higher Moenkopi component, yet have very low Ir contents (Fig. 9). These run contrary to the general argument just made regarding a greater projectile component in impact-melt particles formed higher in the section. Both of these samples were small, and no material remained for major-element analyses; the data plotted are based on clear glass analyses of Hörz et al. (2002). These authors inferred that the M12 and M20 glasses contained a higher Moenkopi component than most clear glasses analyzed, and that their low FeO contents indicated a low projectile component. Our INAA data for K, Ca and Fe on bulk M12 match well the probe data for clear glass (Hörz et al., 2002, Table 3) suggesting that most of the bead was composed of such glass. As discussed above, M12 has anomalous siderophile-element contents, with Co and Ni indicating 35 times more projectile material than indicated by Ir and Au. The bulk data for M20 do not match the glass data very well. Bulk particle M20 has by far the lowest CaO content of any of the impact-melt particles (Table 3), yet the clear glass has among the highest CaO contents (Hörz et al., 2002, Table 3). Altered glass in M20 has much lower CaO contents (Hörz et al., 2002), similar to what we found for the bulk particle. However, the altered glass has much higher Fe contents than the clear glass, and our bulk particle datum matches the clear glass in Fe. Clearly, a simple understanding of the relationship between bulk M20 and the glasses it contains is elusive. M20 also has somewhat anomalous siderophile-element contents (Fig. 6). Thus, M12 and M20 should be treated cautiously when attempting to infer projectile-target mixing details.

There are two impact-melt particles for which we have major-element compositions determined on fused beads for comparison with the clear glasses of Hörz et al., 2002) – M18 and SIG-4 (Fig. 9). Bulk SIG-4 has $(Ca+Mg)/Al$ and $(Ca+Mg)/Si$ very similar to those of the clear glass. We did not note clastic material in this sample, and the data are consistent with the bulk

of the particle being similar to the clear glass. Bulk M18 is very different from its clear glass in major-lithophile-element contents (Fig. 9). The bulk sample contains higher CaO and MgO than does the clear glass, suggesting incorporation of dolomite clasts in the bulk particle. This then implies additional Kaibab component not recorded in the clear glass composition. Thus, it is difficult to determine whether M18 violates the projectile-target mixing generalization discussed above.

One last point regarding comparing our earlier results on glasses with the bulk particles studied here needs to be stressed. Hörz et al. (2002) showed that there are two basic types of glasses in the impact-melt particles, those with low Fe and Ni, and Ni/Fe like that of the projectile, and those with high Fe, low Ni and Ni/Fe much lower than that of the projectile. In contrast, the bulk particles have essentially a continuum of Fe contents covering the total range observed in the glasses, but all have Ni/Fe like that of the impactor. Thus bulk impact-melt particles have variable contents of unfractionated (except for Au) projectile material. Some glasses on the other hand, contain a fractionated projectile component that must be compensated by other phases, probably metal or sulfide blebs, contained in the bulk particle. Electron microprobe analyses of metal blebs in impact-melt particles show that they can be highly enriched in Ni and Co relative to Canyon Diablo metal (Brett, 1967; Kelly et al., 1974; our unpublished data), and can balance the low Ni contents observed in high-Fe, low-Ni glasses observed by Hörz et al. (2002).

Metallic spherules and melting of the projectile

Blau et al. (1973) studied the textures and compositions of a suite of metallic spherules from Meteor Crater. They stated that the dendritic texture demonstrated that the spherules

solidified from a molten alloy, limiting permissible models to those involving quenching of liquid droplets. They noted that the textures of some of the spherules are similar to those observed for Fe-Ni alloys containing C. They also noted that the spherules are enriched in Ni, S and P compared to the metallic phase of the Canyon Diablo meteorite, and suggested that this was due to slight selective melting of troilite-schreibersite-rich regions of the meteorite. Finally, Blau et al. (1973) argued that high Co contents of the spherules compared to Canyon Diablo metal was the result of oxidation of the spherules, enhancing the Ni and Co contents through loss of Fe oxide. This process also led to some oxidative loss of S and P (Blau et al., 1973).

In contrast, Kelly et al. (1974) noted that the S content of the spherules – 9 to 28 mg/g (Blau et al., 1973) – is not enhanced relative to an estimate of the bulk meteorite S content of 22 mg/g. This, coupled with Ni/Co and Ni/Cu ratios like those of the bulk meteorite led Kelly et al. (1974) to conclude that the spherules were formed by melting bulk Canyon Diablo material, not selective melting of troilite-schreibersite-rich regions. Kelly et al. (1974) explained the high Ni, Co and Cu contents relative to bulk meteorite by oxidation and removal of Fe.

A more recent estimate of the bulk meteorite S content is ~9-10 mg/g (Buchwald, 1975, p. 392), about half that estimated by Kelly et al. (1974) based on older modal data. Thus the S content of the spherules may be enhanced by up to a factor of ~3 compared to the bulk meteorite. Buchwald (1975, p. 392) also estimates a bulk meteorite P content of 2.5 mg/g. The spherules contain 7-14 mg/g (Blau et al., 1973), suggesting they may have up to ~6 times the P content of the bulk meteorite. This seems to support the contention of Blau et al. (1973) that some selective melting of troilite-schreibersite-rich regions occurred. However, Blau et al. (1973) did their analyses by electron microprobe using an “integrated line scan technique” on heterogeneous

samples. True bulk spherule S and P contents need to be determined to evaluate whether selective melting of troilite-schreibersite-rich regions occurred.

Figure 10 shows our INAA data on metallic spherules, along with data from Xue et al. (1995). Most spherules form a trend away from bulk Canyon Diablo towards higher Ni but lower Fe, consistent with simple loss of Fe (arrow, upper panel). A few spherules plot below the Fe-loss line. There could be two explanations for this: (i) the samples contained some iron oxides or hydrous oxides that were not removed prior to analysis, or (ii) the spherules are richer in C, P and/or S than bulk Canyon Diablo. Note that the oxide-shell samples analyzed by Xue et al. (1995) plot at a lower normalized Fe abundance than “ideal” limonite, calculated here as $\text{FeO}\cdot\text{OH}\cdot 2.1\text{H}_2\text{O}$, and with higher Fe/Ni than the metal spherules they were taken from (tie lines). This is consistent with enrichment in Fe relative to the metallic core coupled with dilution by a component such as H, O, C, P and/or S. Because the oxide shells have lower bulk Fe than “ideal” limonite, some dilution by C, P and/or S must have occurred.

Cobalt-Ni, Ir-Ni and Au-Ni are well correlated in the spherules (Fig. 10). Kelly et al. (1974) argued that the Co/Ni ratios of the spherules were identical to the bulk metal of Canyon Diablo, and thus slight selective melting of troilite-schreibersite-rich regions did not occur. We find subtle variations in siderophile-element/Ni ratios in the spherules. The Co-Ni trend has a slightly lower slope than the Canyon Diablo ratio, while Au/Ni has a slightly higher slope. Regression lines pass through the mean Canyon Diablo composition (Fig. 10). This is consistent with the oxidation model of Kelly et al. (1974). Cobalt is more oxidizable than Ni. Those spherules with the highest Ni, hence having suffered the most oxidation and loss of Fe, also have Co/Ni ratios lower than bulk Canyon Diablo. Gold is less oxidizable than Ni and shows the opposite – high Au/Ni for the most Ni-rich spherules.

Four spherules have Ni contents lower than bulk Canyon Diablo. They also have the lowest sums of Fe, Co and Ni (Table 5), indicating that they contain larger amounts of diluents than do other spherules. Finally, they have high Co/Ni and low Au/Ni ratios (Fig. 10). All of these characteristics are consistent with their containing a substantial amount of the Fe-rich, Ni-Au-poor oxides produced during spherule formation. One would expect the oxide to form on the outer surface of the spherule. Thus, should these four spherules be enriched in oxides, the Co-Ni-Ir-Au-rich metallic core of the spherule somehow would have been lost during the formation process.

All of the spherules have As/Ni ratios in excess of the Canyon Diablo ratio (Fig. 10), contrary to expectations from an oxidation model. Arsenic is more easily oxidized than Ni and should be depleted relative to it, but Ni-rich spherules have As/Ni ratios of 1.89-2.79 times Canyon Diablo. The As-Ni data also scatter considerably compared to the very linear Co-Ni array (Fig. 10). Our As-Ni data closely mimic the P-Ni data of Blau et al. (1973) (Fig. 10), suggesting that the anomalous enrichment of As may be a result of slight selective melting of schreibersite-troilite-rich regions of the impactor. Arsenic and P are incompatible elements during crystallization of molten Fe-Ni, and thus will be correlated in irons (e.g., Scott, 1972). We did not find data on the As content of schreibersite, but As is in the same chemical group as P, suggesting that schreibersite exsolved from the metal may be enriched in As. Thus, the high As contents of the spherules may support slight selective melting of troilite-schreibersite-rich regions of Canyon Diablo as part of the explanation for the element enrichments.

Canyon Diablo contains troilite-graphite inclusions that are typically rimmed by schreibersite and cohenite (Buchwald, 1975). These inclusions have lower mean density than the surrounding metal. Because of this, a passing shock front will reverberate (e.g., Kieffer,

1971), and result in localized stress and temperature concentrations along metal-inclusion margins (e.g., Melosh, 1989; Stöffler et al., 1991) that will lead to enhanced localized melting at metal-inclusion interfaces. Hydrocode simulations of the Meteor Crater impact show that this will occur along the trailing edge of the impactor at moderate depths below the surface (Schnabel et al., 1999).

We conclude that both selective melting of troilite-graphite inclusions and oxidation and removal of Fe (and other elements) played roles in producing the chemical characteristics of the metallic spherules. Note that Kelly et al. (1974) and we ground off the oxide coating on the spherules before analysis. This was done under the assumption that these coating represented low-temperature rusting of the spherules. In retrospect, this most likely biased the data. The oxide coatings could well represent original high-temperature oxides produced as the spherules were airborne immediately after the impact. By grinding these off, we artificially increased the concentrations of the less oxidized elements that were concentrated in the metallic cores. True bulk analyses of spherules, including the oxide coatings, plus analyses of the different phases in Canyon Diablo are needed to evaluate the origin of the metallic spherules.

Geochemical constraints on the impact process

We have shown that the impact-melt particles contain material from the upper part of the target stratigraphy, that all are consistent with mixtures of Moenkopi and Kaibab rocks, and that those particles that seem to have been derived from lower portions of the melt zone contain less projectile material. These observations allow us to constrain the mechanism of impact melting.

One mechanism for producing dispersed impact-melts is through jetting, a process that occurs when a hypervelocity projectile meets the target at an oblique angle (see Kieffer, 1977;

Melosh, 1989). In the case of Meteor Crater, this geometry could have been satisfied when an approximately spherical Canyon Diablo meteoroid contacted the target surface, or when irregularities on the meteoroid or target surfaces meet (Fig. 11). Jetting occurs from the moment of impact until the projectile has penetrated about halfway into the target (Melosh, 1989). Roddy (1978) calculated the kinetic energy required for formation of Meteor Crater, and from this the projectile size for various assumed impact velocities. The lowest velocity used, 15 km/sec, results in a projectile about 16 m in radius, which sets the approximate maximum depth for jetting. We previously favored a shallow zone of melting for formation of some of the impact-melt glasses, <30 m (Hörz et al., 2002). This is compatible with jetting as the mechanism for formation of these melts. However, none of the impact-melt particles (this study) or the clear glasses (Hörz et al., 2002) contains only Moenkopi plus projectile components. The Moenkopi is estimated to have averaged about 8.5 m thick in the pre-impact target zone (Roddy, 1978), and thus we would expect that some impact-melts would be free of Kaibab material if jetting was the major formation mechanism. Because of this, we do not see a clear role for jetting in the production of impact-melts at Meteor Crater. Note however, that the bulk particles we have studied are mostly large, roughly cm-sized (Appendix 2), and that we found relative few clear, unaltered glasses in the samples we studied petrographically (Hörz et al., 2002). If jetting predominantly produced finer impact-melt spray, our studies could have missed those particles composed only of Moenkopi plus projectile. Thus although we find no clear signature for jetting, neither can we rule it out.

Another mechanism for formation of ballistically dispersed impact-melt particles is along the contact between the deforming projectile and the transient crater floor (Fig. 11). In this case, melting may extend to depths a few times the projectile radius (e.g., Melosh, 1989). The impact-

melts produced by this mechanism would flow up the transient crater wall and potentially mix with a range of target material during this flow. Thus, melts formed after the deformed projectile was entirely below the original target surface would have the projectile component diluted by inclusion of additional target material, including clasts. To some extent, this is compatible with our data on bulk particles. Those particles with the lowest normalized Ir content (lowest projectile component) have the strongest Kaibab signature, suggesting formation deeper in the transient crater.

Because the melt-mixing process is so chaotic, clear signatures are not preserved in the impact-melt particles. We believe our data are compatible with both jetting and melting at the transient crater-deforming projectile interface as being important in the formation of the ballistically dispersed impact-melt particles at Meteor Crater.

CONCLUSIONS

Ballistically dispersed impact-melt particles from Meteor Crater are dominantly composed of three components: the Canyon Diablo projectile, and target-rock from the Moenkopi and Kaibab formations. The compositions of the impact-melt particles do not require that rocks from the lower portions of the target section – the Toroweap and Coconino – be mixed in the melts. Although the data do not rule out up to 10% contribution from these rocks, the compositions of the impact-melt particles indicate formation only in the upper portion of the section, above these sandstones.

The impact-melt particles contain substantial projectile material. Our best estimate is that bulk particles contain on average ~14% Canyon Diablo iron, with a maximum of 20-22%. This is higher than we previously found for ballistically dispersed impact-melts from the much

smaller Wabar Crater (Mittlefehldt et al., 1992). The siderophile-element ratios are essentially unchanged from those of Canyon Diablo iron, except for Au. Many samples have Au/Ni and Au/Ir ratios much lower than for the projectile. The lowest ratios are found for impact-melt particles with the highest Kaibab component. The Br contents of Kaibab rocks are higher than those for other rocks in the section, and we suggest that fractionation of volatile Au halides may be the cause of the Au fractionation.

Metallic spherules are generally enriched in Co, Ni, Ir and Au compared to Canyon Diablo metal. Element/Ni ratios show subtle deviations from Canyon Diablo ratios that are inversely correlated with oxidizability of the element relative to Ni. We attribute this to partial oxidation of molten metal spherules during flight. Because we ground off oxide coatings from the spherules prior to analysis, our data are biased in favor of the metallic cores. The spherule compositions are consistent with slight selective melting of schreibersite-troilite-rich regions of the projectile, and this can be explained by enhanced shock melting of lower density troilite-graphite-schreibersite inclusions present in Canyon Diablo.

ACKNOWLEDGMENTS

We thank The Barringer Crater Company for permission to do field work in Meteor Crater, and the late D.J. Roddy for guiding our field collection. The senior author thanks J.H. Jones and A.H. Treiman for accompanying him in the field. We thank C.B. Moore and the Center for Meteorite Studies, ASU, for providing the impact-melt particles and metallic spherules studied here. The NASA Cosmochemistry Program supported DWM, and the Planetary Geology and Geophysics Program supported FH in these studies.

APPENDIX 1. TARGET ROCKS

Sample K-1, K-2 and C-1 through C-4 (Table 2) are small hand samples of Kaibab and Coconino that had been collect by Hörz many years ago as representative samples of these formations. Their collection locations are undocumented. Samples labeled Ma, Ka, Ta, Ca etc. are from a systematic stratigraphic section collected by Hörz and See specifically for this study. Details on these samples are given in See et al. (2002). The remaining samples described below were collected by Mittlefehldt from the crater and its vicinity.

- MC-01: Moenkopi. Light pink, massive sandstone collected from the north crater wall, ~2-2.5 m above the contact with the Kaibab.
- MC-02: Coconino. White, somewhat frothy and powdery sandstone fallback deposit collected from the shaft dump on the crater floor.
- MC-03: Coconino. Shattered gray sandstone collected from the southwest crater wall ~70 m below the Kaibab.
- MC-04: Coconino. Gray matrix of shattered sandstone collected ~10 m above sample MC-03.
- MC-05: Coconino. Gray sandstone collected from the southwest crater wall ~5 m below the Kaibab.
- MC-06: Kaibab. Shattered gray dolomite collected from the southwest crater wall ~15 m above the base.
- MC-07: Moenkopi. Reddish siltstone/clay-rich facies collected from block in talus, southwest crater wall.
- MC-08: Toroweap. Gray sandstone collected from the overturned flap on the southwest crater rim.
- MC-09: Coconino. Highly shocked ejecta debris collected from south crater rim.

- MC-10: Kaibab. Gray dolomite collected from overturned flap on the west crater rim.
- MC-11: Coconino. Gray sandstone collected from stream cut, Oak Creek Canyon.
- MC-12: Kaibab. Gray dolomite collected from boulder float in stream cut, Oak Creek Canyon.
- MC-13: Toroweap. Knobby gray sandstone collected from the overturned flap on the southwest crater rim.

APPENDIX 2. IMPACT-MELT PARTICLES

- H11: This is a composite of 15 individual irregularly shaped cm-sized impact-melt particles. The particles are vesicular with dark gray interiors, and thin brownish rims. The particles were individually ground, and the powders mixed and homogenized to produce a bulk sample with a total mass of about 4 grams.
- H11a: This is an individual cm-sized irregularly shaped impact-melt particle from the same group used to prepare H11. This particle was much harder to grind than the others, and was kept separate for that reason.
- IIG-1: This is an irregularly shaped dark brown vesicular impact-melt particle ~1.8x1.3x1.3 cm in size. Vesicles are up to ~4 mm in size. Numerous small clasts are present. Some secondary minerals are present both on the surface and in interior vesicles. Two samples (IIG-1a and IIG-1b) were hand-picked from the freshest material.
- IIG-2: This is an irregularly shaped dark brown impact-melt particle ~1.8x1.4x1.4 cm in size containing very few vesicles, generally ~1-2 mm in size. Numerous small clasts are present. Some secondary minerals are present both on the surface and in interior vesicles. Two samples (IIG-2a and IIG-2b) were hand-picked from the freshest material.
- IIG-3: This is an irregularly shaped dark brown impact-melt particle ~1.9x1.1x1.1 cm in size containing few vesicles generally ~1 mm or less in size. Little clastic material is present. Some secondary minerals occur both on the surface and in interior vesicles. Four samples (IIG-3a through IIG-3d) were hand-picked from the freshest material.
- IIG-4: This is a smooth, but highly irregularly shaped impact-melt particle. The particle is composed of black to red-black glass and yellow-brown material that appears to be melted clastic debris. The interior is cored with this melted clastic material. A fairly

pure impact-glass sample (IIG-4) and a fairly pure clast sample (IIG-4c) were hand-picked.

- M1: Large (7 mm) accretionary sphere of black glass with many accretionary promontories and splashes. Some of the latter are flattened and transitional to the dark matrix glass, giving the surface a somewhat swirly appearance. One side is rough, the other is smooth. The bead is vesicular and almost a hollow shell. Some of the interior surfaces and interior small vesicles contain fine-grained secondary minerals.
- M2: Beautifully flattened, large (5x3 mm) dense black shiny spheroid with sugary surfaces on all sides. It contains no prominent accretions, but has one hemispherical depression. The bead is very magnetic, and is an oxide bead.
- M3: Large (9 mm) fairly rounded bead of brownish color. Upon splitting, the interior is highly porous and appears weathered with a distinctly orange, oxidized skin. This exterior surface is dull, pitted and of sugary appearance. Some quartz clasts are present. Samples M3a and M3b are two different samples of hand-picked material.
- M4: Large (8 mm) ellipsoid of dark glass with somewhat grayish hue. It appears to be a mixture of dark glass and a lighter grayish glass. Many accretionary particles are present on all sides. The interior is vesicular and nearly hollow, and contains secondary minerals. There is a patch of fine-grained, white sugary material that may be a glassy clast. Sample M4a is hand-picked glassy material, while M4b is hand-picked material enriched in secondary minerals.
- M5: Stubby ellipsoid (4 mm), possibly stubby cylinder of dark colored, fresh-appearing glass. The surface is dull and sugary with many small holes or pits. The interior is very porous,

essentially frothy. Accretionary features are abundant and display a bi-modal distribution. Interior vesicles contain some secondary minerals.

- M6: Large (12 mm), broken, ropy and cylindrical lapillus of dull glass with a pitted surface. There are many accretionary particles on the surface, and a few clasts are present. A fresh fracture surface displays two types of material; a dark, very porous glass matrix and tan inclusions, either of melt or finely crystalline material (weathered?).
- M7: Exceptionally nice, round sphere (3 mm) of dark glass with numerous accretionary beads. A modestly lighter colored glass makes distinct promontories and knobs. The interior is very porous at microscopic scales. There are some clasts in the interior, and a small amount of fine-grained secondary minerals.
- M8: A classic “impactite” of Nininger: highly porous, slag-like, weathered glass of brown color containing numerous pockets of clasts and distinctly different colored melts. The rim is modestly oxidized. This sample was very friable. Sample M8a is hand-picked coarse fragments from the sample crushing, while M8b is the fine debris produced during crushing.
- M10: A typical dull, dark colored impactite. It is coarsely porous and somewhat weathered with an oxidized rim, but only a small amount of fine-grained secondary minerals.
- M11: A large (12-15 mm) flattened ellipsoid of porous, tan melt. The surface is unusually sculptured with polygons forming an almost cauliflower-like texture. Some of the polygons are of dark melt, but the majority is light-tan in color. The sample is highly altered.
- M12: An impact-melt particle of unusually fresh, tektite-like, dense glass of black color, almost volcanic in appearance. The sample is very fresh, and clast-poor; possibly clast-free.

- M13: A very large (14 mm) typical impactite of rusty-brown colored glass. The surface is dull and sugary in appearance with no good accretionary features but is definitely an aerodynamically shaped particle. The interior is frothy and has a red colored weathering rind surrounding a dark gray/black core. Sample M13a is reddish rind glass, while M13b is black interior glass.
- M14: A large (8 mm long) elongated, ropy lapillus fragment. The surface has numerous weathered knobs of dull, dust-covered secondary material and some clasts. There are two types of glass; dark glass and honey-yellow glass. The interior is frothy, with little clastic material.
- M15: A large, ropy lapillus fragment (about 15 mm long) with many accretionary surface features mostly of dark glass. Some patches of secondary minerals are present on the surface. The interior shows yellowish weathering rind glass with a fresh black glass core. Some clastic material is present in the particle. The sample was very tough to break.
- M16: A distinctly rusty-colored, highly porous aerodynamically shaped melt object. It does not have distinct dense skin; most of the particle is altered, with only a little fresh, dark gray to black glass in the interior. It contains some clastic material (quartz).
- M17: A large (11 mm) ropy, elongate lapillus of dense dark melt with many accretionary knobs on the surface. The interior includes fresh black glass plus reddish, altered glass.
- M18: A large ovoid lapillus (16 mm) with a grayish-white surface due to partial coating by secondary minerals, and bleaching of the underlying glass. Numerous honey-colored pockets are visible. The fresh fracture surface reveals intimate mixing of the different colored glasses, but the particle contains a distinct, bleached rind. Sample M18a is hand-

- picked interior glass, but containing some bleached glass; M18b is enriched in the bleached glass; M18c is exterior material enriched in secondary minerals.
- M19: A flat, pancake shaped object displaying prominent ridges showing material flow and aerodynamic shaping. The interior is porous, somewhat weathered black glass with a distinctly rusty-colored, orange oxidation rim. Some secondary minerals are present on the exterior.
- M20: A small irregular fragment of dense mostly honey-colored glass. Part of the exterior surface is preserved and the fragment was clearly derived from some sort of ballistic bead.
- M21: A very fresh appearing bead of yellow glass with knobs and accretionary promontories of both black and yellow glasses, i.e. a mixed melt. No secondary minerals are present.
- M22: This sample is a hollow hemisphere – a fragment of a hollow sphere - with a smooth outer surface. The interior glass is dark and contains numerous microvesicles.
- M23: An elongate bead of yellow glass with prominent accretionary knobs. Some black glass is present in the interior.
- M24: A large (9 x 2 mm) dumbbell of relatively dense, dark glass, somewhat sugary, and with a pitted surface. A very thin weathering rind is present.
- M25: A fresh, small (3-4 mm) bead of dark glass with a distinctly shiny surface. The distribution of accretionary features is uneven. The interior contains some vesicles, and a few clasts.
- M26: This is a cylindrical object of unusual dark wine-red color. The particle is fairly fresh with shiny surfaces and no prominent accretionary features. The interior contains some black glass.

M27: This is a very fresh sphere of dense dark glass with a smooth, shiny surface. The interior is composed of fresh dark frothy glass, with a thin alteration rind.

SIG-1: This is an oblong hollow spheroid ~5x4x4 mm in size with a few protuberances. One end contains many <1 mm size vesicles. The interior cavity is filled with secondary minerals. Several fresh, black glass fragments were hand-picked for analysis.

SIG-2: This is an almost perfect hollow sphere ~4 mm in size with a few protuberances and many <0.5 mm size vesicles. This sample contained relatively little secondary material. One piece of fresh glass was hand-picked for analysis.

SIG-3: This is a flattened (on one side) spheroid ~5 mm in size with a large protuberance on the flattened side. There are a few <1 mm size vesicles. This sample was partially hollow – a clast occupies part of the center. Several fragments of impact glass were selected for analysis (SIG-3) and a sample of secondary minerals was selected (SIG-3w).

SIG-4: This is a slightly vesicular smooth brown glass hollow ball. There is a red-brown weathering rind surrounding fresh black glass. The interior cavity is small, and partially filled with white secondary minerals.

APPENDIX 3. INAA DATA ON MISCELLANEOUS SAMPLES

TABLE A1. COMPOSITIONS OF MISCELLANEOUS SAMPLES FROM METEOR CRATER DETERMINED BY INAA*.

*Note in this table Ni is given in units of mg/g. Individual uncertainties given in the ± columns.

[†]mass refers to mass in mg of analyzed material and represents most or all of the mass of sample prepared.

[‡]clast - lithic clast separated from impact melt particle IIG-4; sec min - secondary minerals found in impact melt particles SIG-3, M4 and M18; oxide - rounded oxide bead.

*Note that in this table Ni is given in units of $\mu\text{g/g}$. Ir in all target rocks was below the 2σ detection limit of ~ 1 ng/g. Typical 1σ relative uncertainties are: $\leq 2\%$ - Na, Sc, Fe, Co, La, Sm; 1-3% - Cr, As, Cs, Ce, Eu, Yb, Hf, Th, U; 2-5% - K₂O, CaO, Zn, Sb, Ba, Tb, Lu, Ta; 4-8% - Br, Rb; 5-10% - Se; 5-20% Sr, Au; 10-20% - Zr, Nd W; 15-50% - Ni. Values in italics have uncertainties 1.33-3 \times the upper end of the typical uncertainty range. Underlined values have uncertainties 3-6 \times the upper end of the typical uncertainty range. In all cases, the proper number of significant digits are used.

[†]mass refers to weight in mg of analyzed material; samples were splits of homogenized powders of much larger mass.

*Note that in this table Ni is given in units of mg/g. Typical 1 σ relative uncertainties are: $\leq 2\%$ - Na, Sc, Fe, Co, Ni, La, Sm; 1-3% - Cr; 1-4% - As, Ce, Eu, Hf, Ir; 1-5% - Yb, Au; 2-6% - K₂O, CaO, Lu; 2-8% - Ba, th; 2-12% - Tb, U; 2-16% - Cs; 4-5% - Sr; 4-12% - Sb; 5-20% - Zn, Br, Ta; 10-35% - Zr; 10-50% - Rb, Nd, W; 25-45% - Se. Values in italics have uncertainties 1.33-3 \times the upper end of the typical uncertainty range. Underlined values have uncertainties 3-6 \times the upper end of the typical uncertainty range. In all cases, the proper numbers of significant digits are used.

[†]mass refers to weight in mg of analyzed material and represents most or all of the mass of sample prepared. H11 is an exception; this is a split of homogenized powder prepared by combining 15 impact-melt particles.

[‡]Samples IIG-1a, IIG-1b etc. and M3a, M3b are different splits of individual impact-melt particles run as homogeneity tests. Sample M8a is hand-picked fresh interior glass, while M8b is fine dust produced during crushing of an individual impact-melt particle. Samples M13a and M13b are respectively exterior and interior sample pairs from an individual impact-melt particle. Samples M18a and M18b are respectively interior and exterior sample pairs from an individual impact-melt particle. H11a is an individual impact-melt particle from the same group as used for sample H11.

FIGURE CAPTIONS

- Figure 1. Variation in major-element compositions of Meteor Crater target rocks with depth demonstrating the unique geochemical characteristics of the different formations. On this and all subsequent figures, the data are adjusted to a volatile- and Fe-free basis to correct for differences in CO₂ and H₂O in the target rocks, and differences in projectile components in impact-melt particles. See text for a discussion of the rationale for adjusting the data. Note that Mg and Ti are plotted on log scales. Data from See et al. (2002).
- Figure 2. Variation in trace-element compositions of Meteor Crater target rocks with depth demonstrating the unique geochemical characteristics of the different formations.
- Figure 3. Major-element variation diagrams comparing Meteor Crater target rocks with impact-melt particles demonstrating that the Moenkopi and Kaibab Formations are the major target-rock contributors to the impact-melt particles. The inset in the Mg vs. Al diagram shows that mixing of at most 10% of Coconino Formation could be hidden in the scatter of the data, but no Coconino or Toroweap components are required by the data. Some target-rock data from See et al. (2002).
- Figure 4. Ca vs. Sc, Ca vs. Ta, and Ta vs. Sc diagrams comparing Meteor Crater target rocks with impact-melt particles, further demonstrating that the Moenkopi and Kaibab Formations are the major target-rock contributors to the impact-melt particles.
- Figure 5. Ca vs. trace-element diagrams comparing Meteor Crater target rocks with impact-melt particles. Secondary mineral data are from Appendix 3.
- Figure 6. Element-element diagrams for siderophile elements in Meteor Crater impact-melt particles, showing data for impact-melt particles from Wabar Crater (Mittlefehldt et

al., 1992) and Wolfe Creek Crater (Attrep et al., 1991) for comparison. The data are normalized to the projectile composition. The Meteor Crater samples have Co/Ni and Ir/Ni ratios equivalent to the Canyon Diablo iron, but show strong fractionations in Au/Ir.

Figure 7. Co vs. Au/Ni for impact-melt particles. Particles covering nearly the entire range in Au/Ni ratios can have similar Co contents, and samples with similar Au/Ni can have substantially different Co contents. Thus the Au/Ni fractionation is not related to the mixing ratio of projectile and target materials.

Figure 8. Au/Ir vs. (Ca+Mg)/Si of impact-melt particles shows that those particles with a high dolomite component tend to have lower Au/Ir ratios. Br vs. (Ca+Mg)/Si of target rocks shows that the halide Br is roughly correlated with the dolomite content of the target rock. Together, these suggest that volatilization of Au-halides may be responsible for the observed fractionation.

Figure 9. Variations in (Ca+Mg)/Si and (Ca+Mg)/Al with depth in target rocks (left) and with Ir content in impact-melt particles (right). Dashed lines labeled K mark the lower limits of (Ca+Mg)/Si and (Ca+Mg)/Al observed for Kaibab samples, while the line labeled M marks the upper limit of (Ca+Mg)/Si in Moenkopi samples – all Moenkopi samples have (Ca+Mg)/Al < 3.

Figure 10. Siderophile-element data for metallic spherules compared to the Canyon Diablo iron. Most spherules have Fe and Ni contents that follow a trend of Fe loss (arrow, upper diagram). Some samples with low Fe are consistent with dilution by oxides. Equivalent normalized Fe contents for hematite, goethite and limonite are shown for comparison. Co-Ni, Ir-Ni and Au-Ni are highly correlated, with most samples

enriched in these elements compared to the Canyon Diablo iron. Dashed lines are regression lines through the Co-Ni and Au-Ni data. The slopes of these lines are consistent with expectations from a simple oxidation model (see text). The metallic spherules show enrichments in As that are inconsistent with a simple oxidation model, but closely mimic the P-Ni trend. This suggests that some selective melting of schreibersite-troilite-rich regions of Canyon Diablo may have occurred (see text). Some data are taken from Blau et al. (1973) and Xue et al. (1995).

Figure 11. Schematic diagrams indicating two possible mechanisms for formation of impact-melt particles at Meteor Crater. Jetting occurs at the point of contact between the projectile and target where they meet in oblique angles. Jetting will occur only until the projectile penetrates to a depth approximately equal to its radius (Melosh, 1989). Based on estimates of the pre-impact stratigraphy and projectile size, the thickness of the Moenkopi may have been roughly $\frac{1}{2}$ the projectile radius. Thus jetting ought to have produced some impact-melt particles composed dominantly of Moenkopi plus meteorite. We have not found any of these, but the compositions of some melts indicate formation at shallow levels of the target. Impact-melts will also form at the interface between the deforming projectile and the transient crater wall, and the melt zone will extend a few projectile radii below the surface (Melosh, 1989). Flow of the melt up the transient crater wall will promote mixing. The data suggest that many of the particles were formed by this latter mechanism.
